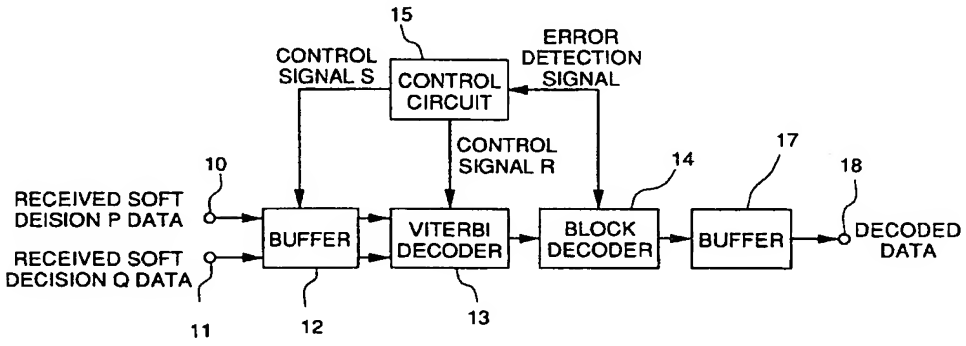
(54) Data error correction system

(57) A data error correction system is provided which is capable of executing repeated error correction processing, and which improves the quality of communication lines by allowing repeated corrections of errors generated in the transmission line.

The data error correction system comprises a Viterbi decoder 13 for decoding a designated encoded data from a buffer 12 and a block decoder for executing decoding of the data corresponding to a length of a block code after being decoded from the Viterbi decoder 13, when error correction is possible. When error correction is not possible, the data error correction system controls execution of re-decoding by the Viterbi decoder for executing error correction of the data corresponding to a length of a block code whose correction has not been possible yet at this stage.

Fig. 1



EP 1 017 180 A2

Description

BACKGROUND OF THE INVENTION

Field of the Invention

[0001] The present invention relates to a data error correction system which is used for improving the line quality of a transmission line by coding data into errors correction codes so as to correct errors generated in the transmission line in so far as possible, in the fields of satellite communication and space communication which transmit data such as compressed image data.

Background Art

[0002] There is a data error correction method in the digital communication, called "Vitabi decoding method (G. D. Forney. Jr., "The Viterbialgorithum", Proceedings of IEEE, vol. 61, pp. 268-278, Mar. 1973). In order to improve the capability of the error correction, a connected code, which is a combination of a convolutional code with the other code, is proposed by G. D. Forney. Jr. Another connected code generally used is a connection of a convolutional code and a Reed-Solomon code, which is obtained by combining a block coder and a Reed-Solomon coder. The decoding of the coded data is carried out based on the Viterbi algorithm and the Viterbi decoded data is subjected to Reed-Solomon decoding.

[0003] However, since the error correction is executed independently by the Viterbi decoder and by the Reed-Solomon decoder, the above-described conventional data error correction system entails the problem, that it is not possible to obtain a sufficient error correction effect and thus to improve the line quality of a transmission line.

[0004] It is therefore an object of the present invention to solve the above described problem, and to provide a error correction system which is capable of correcting data errors repetitively, sufficiently correcting bit errors generated in the transmission line, and improving the line quality.

SUMMARY OF THE INVENTION

[0005] According to the first aspect of the present invention, a data error correction system comprising: a buffer for receiving data which are encoded by a block encoder and a convolutional encoder; a Viterbi decoder for decoding a block of data designated from the data output from said buffer in accordance with the Viterbi algorithm; a block decoder, which starts decoding when it receives data corresponding to a block code length from said Viterbi decoder, for executing the error correction when possible and outputting the result to a block decoder; and a control circuit for controlling execution of re-decoding by said Viterbi decoder so as to execute decoding by said block decoder for data corresponding to the block code length whose error could not be corrected yet, based on an error detection signal output by said block decoder, when the error correction has not been possible.

[0006] According to the second aspect of the present invention, the data error correction system according to the first aspect, wherein the data error correction system allows repeated executions of decoding by the Viterbi decoder and the block decoder by said error detection circuit until the error correction is enabled, when the second error detection has not been possible.

[0007] According to the third aspect of the present invention, the data error correction system according to the first aspect, wherein data input into said buffer is the bit data expressed by soft decision representation.

[0008] According to the fourth aspect of the present invention, the data error correction system according to the first aspect, wherein said Viterbi decoder comprises: a branch-metric generator for obtaining a probability of the case in which each transmittable symbol have been transmitted, when the data for respective symbols output from said buffer are received; a path-metric register which stores the cumulative metrics of the survival path; an addition comparison selection circuit for outputting a path-metric value at the n state and a selection information at the n state selected by executing comparison, addition, and selection of outputs of said path-metric register and said branch-metric register at every symbol time along the trellis line figures; a maximum likelihood path state number order detector for obtaining a state number which has the maximum path-metric value among path-metric values at the n state output from said addition comparison selection circuit; a path memory for storing at every symbol time the selection information at the n state output from said addition comparison selection circuit; a trace back circuit for outputting a decoded data with (u+k) bits from the last bit that arrived when tracing back to the past from the state number output of the the maximum likelihood state number order detector at every (u+k) time, when the encoded data are divided at each k bits and u bits as the redundancy bit are added; and a decoding control circuit for allowing execution of re-decoding when receiving a control signal from said control circuit.

BRIEF DESCRIPTION OF THE DRAWINGS

DETAILED DESCRIPTION OF THE INVENTION

[0010] Hereinafter, an embodiment of the present invention will be described with reference to the attached drawings.

[0011] Figure 1 shows a data error correction system of the present invention. Numerals 10 and 11 denote input terminals for inputting received P data and received Q data, respectively; 12 denotes a buffer for inputting the output of a convolutional encoder, that is, received P data and received Q data, which contains a bit error generated in a transmission line; 13 denotes a Viterbi decoder which executes decoding of an input of the designated received P data and designated received Q data output from the buffer 12 according to the Viterbi algorithm; 14 denotes a block decoder which executes decoding of the decoding data having a length corresponding to a block code of the Viterbi decoder 13; 17 is a buffer for outputting the decoded data from the block decoder 14 to the outside.

[0012] The numeral 15 denotes a control circuit which receives a detection signal that is output from the block decoder 14 when it is decided that the error cannot be corrected at this point, outputs a control signal R such that the Viterbi decoder 13 repetitively executes re-decoding at a predetermined number of times, and outputs a control signal for the Viterbi decoder to output the designated received P data, and the designated received Q data to the buffer 12. The Viterbi decoder 13 is formed as shown in Fig. 3. In Fig. 3, 14 denotes a branch-metric generator for obtaining probabilities of transmitting each symbol in the case each transmittable symbol is transmitted, when data for every symbol output from the buffer 12 is received; 43 denotes a path-metric resistor which stores a cumulative metric of surviving paths; 42 is a addition comparison selection circuit (hereinafter, called ACS circuit) for executing addition (ADD), comparison (COMPARE), and selection (SELECT) for the output from the branch-metric generator 41 at every symbol times and the output of the path-metric resistor 43 according to the trellis diagram, and for outputting the thus compared and selected n-state path-metric value and n-state selection information.

[0013] Furthermore, in Fig. 3, 44 is a maximum likelihood state number order detector for obtaining the state number having the maximum path-metric value among path-metric values in the n-state output of the ACS circuit 42; 45 is a path memory for storing the selection information on the output at the n-state from the ACS circuit 42 at every symbol time; 46 is a trace back circuit which outputs the (u+k) bits as the decoded data from the last bit finally reached by tracing the path memory 45 from the state number output from the maximum likelihood path state number order detector 44 toward the past for g symbol time; 47 denotes a re-decoding circuit 15 for executing re-decoding when receiving the control signal R from the control circuit shown in Fig. 1.

[0014] Next, the operation will be described. For explanatory purposes, it is assumed that the block encoder 32 divides the data every k bits, and adds u bits as the redundancy bits to each k bits, and it is also assumed that the coding ratio R and the restriction length K of the convolutional encoder 33 are fixed at R=1/2 and K=3, respectively.

[0015] First, an explanation of the error correction encoder at the sending side is described. At the sending side, as shown in Fig. 2, data is input into the block encoder 32 through the input terminal 31.

[0016] As shown in Fig. 5, the block encoder 32 executes encoding so as to add u bits of the redundancy bit, c1, c2,..., cu to the first k bits, i1, 12, ... 1k, and add cu+1, cu+2, ..., c2u bits as the redundancy bits to the following k bit, ik+1, ik+2, ..., i2k.

[0017] Subsequently, the output of the block encoder 32 is encoded by the convolutional encoder 33 constructed by a three stage shift register and an exclusive OR. That is, in this convolutional encoder 33, the output of the block encoder 32, as shown in Fig. 4, is entered into the shift resistor 50 at every symbol time, and the outputs of designated stages are subjected to logic processing at exclusive ORs 51 and 52, and P data, P1, P2, ... and Q data, Q1, Q2, ... are output from the output terminals 55 and 56. P data and Q data which are the output of the convolutional encoder 33 are transmitted for inputting to the buffer 12 through the input terminals 10 and 11 of the error correction decoder. At this time, those P data and Q data are represented by the soft decision expression for transmitting to the Viterbi decoder 13 how these data are varied by the noise generated during transmission. Fig. 9 illustrates the soft decision representation of "0" and "1" by

three bits.

[0018] Next, the operation of the Viterbi decoder 13 is described. Fig. 6 illustrates a trellis representation of the convolutional encoder 33. {0, 0}, {0, 1}, {1, 0}, and {1, 1} in the left column of Fig. 6 represent the contents of the first and second steps {a, b}. The values shown on the right side of the arrows are obtained by calculating the formula (a x 2 + b), and these values are called hereinafter the state number. Fig. 6 is explained briefly as follows. When the state number is 0, and if the data input to the convolutional encoder 33 is "0", transition occurs to the state number 0, and the output value "0 0" (the numeral shown on the line indicating the transition from the state number 0 to the state number 0) of the P data and Q data are output. When the input data is "1", transition occurs to the state number 1 and the output value "1 1" is output. Regarding the other state numbers, a destination of the transition is determined in accordance with the data input into the convolutional encoder 33, and the output values of the P data and Q data are shown on the transition lines. The Viterbi decoder carries out a decoding processing according to the diagram shown by the trellis representation.

[0019] That is, when the soft decision P data and Q data are input into the Viterbi decoder 13 from the buffer 12 by a control signal S from the control circuit 15, the branch metric generator 41 calculates branch metrics for the soft decision data P1 and Q1, that is, probabilities of the transmission data set (P, Q) has been (0, 0), (1, 0), (0, 1), (1,1). For soft decision data P1 and Q1, the branch metric at the time when the transmission data set is (0, 0) is made λ 0, the branch metric when the transmission data set is (1, 0) is λ 1, the branch metric for the transmission data set of (0, 1) is made λ 2, and the branch metric for the transmission data set of (1, 1) is made λ 3.

[0020] The branch-metric generator 41 outputs these branch-metrics λ 0, λ 1, λ 2, and λ 3 to the ACS circuit 42. As shown in Fig. 7, the path-metric values of each state number at time m0 are made Γ 0 (m0), Γ 1 (m0), Γ 2 (m0), and Γ 3 (m0). The path-metric register 43 outputs these path-metrics Γ 0 (m0), Γ 1 (m0), Γ 2 (m0), and Γ 3 (m0) to the ACS circuit 42. The ACS circuit 42 carries out an operation based on the trellis representation shown in Fig. 7. That is, the transition merging in the state number 0 at time m1 includes those from the state number 0 and the state number 2. Since the output data from the convolutional encoder at the time of the transition from the state number 0 is "0 0", the branch metric at this time is λ 0, and since the output data from the convolutional encoder at time of the transition from the state number 2 is "1 1", the branch metrics is λ 3. The path-metrics of the state numbers 0 and 2 at time m0 are Γ 0 (m0) and Γ 2 (m0), and after carrying out computation of Γ 0 (m0) + λ 0 and Γ 2 (m0) + λ3, the larger value obtained by the above computation is stored in the path-metric register 43 as the path-metric value Γ 0 (m1) of the state number 0 at time m1.

[0021] The branch values selected simultaneously (the value is "0" when the path indicated by the solid line is selected, and the value is "1" when the path indicated by the broken line is selected) are stored in a path memory 45 as the branch value S0 (m1). Following, the path-metric values Γ 1 (m1), Γ 2 (m1), Γ 3 (m1) and branch values S1(m1), S2(m1), S3(m1) at time m1 are obtained by the same processing, the path-metric values are stored in the path-metric register 43, and the branch values are stored in a path memory 45. The path memory 45 has a memory capacity capable of storing the branch information within the time period mg. The ACS circuit 42 outputs the path-metric values Γ 0 (m1), Γ 1 (m1), Γ 2 (m1), and Γ 3 (m1) at time m1 to the path-metric register 6 as well as the maximum likelihood path state number order detector 44. This is the end of a series of processes (hereinafter, called ACS processing). When the next soft decision data P2, and Q2 are input, the ACS processing described above is repeated. When the processing is completed, the control circuit 47 gives the next order.

[0022] The maximum likelihood path state number order detector 44 outputs to the trace-back circuit 46 the state number having the maximum path-metric values among the maximum likelihood path-metric values Γ 0 (mg), Γ 1 (mg), Γ 2 (mg), and Γ 3 (mg). If there are two or more state numbers which have the same maximum path-metric values, the lowest state number is selected. When the state number having the maximum path-metric values at time mg is "2", the trace-back circuit 46 traces back at time mg along the solid line the paths extending from the state number 2, having the maximum path-metric values, as shown in Fig. 8, while reading the contents of the path memory.

[0023] The trace-back circuit 46 reads the data stored at the state number 2 at time m(g-1) in the path memory 45 to examine whether the path merging to the state number is the state number 1 or the state number 3, and knows that the state number is 1. By repeating the same processing, the path is traced back to the time m0, and finally outputs the (k + m) segments of data (corresponding to the data from the time m1 to the time (k + m)) obtained from the path memory 45 as the decoded data (hereinafter, called trace back processing).

[0024] Furthermore, the path memory 45 is provided which can carry out a reading operation in the ACS processing and a reading operation in the trace-back processing simultaneously. Since the path memory is configured in a ring structure having a memory capacity for the time period of (g + f), the necessary data are not replaced by the ACS processing. Whenever the ACS processing is carried out for the time period g, the decoded data are output after the trace-back processing. The (m+u) bits of decoded data from the Viterbi decoder 13 are delivered to the block decoder 14.

[0025] The block decoder 14 starts decoding for the

(m+u) bits of decoded data, and if the error can be corrected, only k bits of an image data are output to the buffer 17. If the error correction is not possible, the error detection signal is sent to the control circuit 15. When the control circuit 15 receives the error detection signal, the control signal R is then sent to the control circuit 47 in the Viterbi decoder 13.

[0026] When the control circuit 47 receives the control signal R, the maximum likelihood path state number order detector 44 makes the trace-back circuit 46 output the state number having the next largest path-metric value. If there are two or more state numbers having the same maximum path-metric values, the next lowest number to the previous one is selected. If the state number having the next maximum path-metric value following the state number 2 having the maximum number at time mg is "0", the trace-back circuit 46 traces back the path extending from the state number 2, while reading the contents of the path memory 45. The trace back circuit 46 reads the data stored at the state number 0 at time m(g-1) in the path memory 45 to examine whether the path merging to the state number 0 is the state number 0 or the state number 2, and knows that the state number is 0.

[0027] The trace back circuit 46 traces back the path to the time m0 by repeating the same operation, and finally outputs the (k+m) segments of data (corresponding to the data from time m1 to time m(k+m)) as the decoded data. The block decoder 14 receives the (m+u) bits of decoded data from the Viterbi decoder 13, and starts decoding. If the error correction is executed, only k bits of data information are output to the buffer 17. If the error is not corrected, the error detection data is sent to the control circuit 15, and the above operations are repeated until the error is corrected or equal to the number of the state number. If the error is not corrected after the operations are repeated equal to times as the number of the state number, (k+u) bits obtained by the first trace-back processing are output to the buffer 17.

[0028] The control circuit 15 then sends the control signal 1 to the buffer 12, and the buffer 12 outputs in sequence the received soft decision P data and Q data to the Viterbi decoder 13. The Viterbi decoder 13 decodes the next (k+u) bits and examines the probability of the (k+u) bits in order to output the result to the buffer 17. The buffer 17 outputs the decoded image data through the output terminal 18. The presence of one type of buffer 12 and the presence of another type of buffer 17 are to absorb the fluctuation during decoding operation depending upon the amount of the bit errors generated in the transmission line.

[0029] In the above embodiment, although the case is described when the trace-back processing in the Viterbi decoder 13 is carried out for every (k+u) bits, it is possible to carry out the trace-back processing for a smaller unit than (k+u) bits. By reducing the unit size, it is possible to clarify the position of the error data in the (k+u) unit in the repeating error correction when the block decoder 14 sends the error detection signal, which results improving the error correction capability. In addition, by limiting the number of error correcting bits (for example, when a error correcting signal capable of correcting four bits, the error correction is carried out for 3 bits and in the case of four bit error, the error detection signal is output), it is possible to clarify the unit of (u+k) bit to be corrected, which facilitates executing error correction by repeated decoding. Moreover, it is possible to reduce the scale of the circuit using a error detection code adding one parity bit without using the error correction codes.

[0030] As described above, the error correction system of the present invention comprises a block encoder, a buffer for receiving data encoded by the convolutional encoder, a Viterbi decoder for receiving the data designated by the buffer and executing decoding of the data, and a block decoder that starts decoding when it receives the data at a length of the block code length and executes if the error correction is possible. When the error correction is not possible, the system is designed such that the control circuit controls the Viterbi decoder to control execution of re-decoding for a block length of data which has been rendered impossible for error correction. Such a construction makes it possible to repeat the error correction operation after judging evaluating the reliability of the data decoded by the Viterbi decoder, and makes it possible to correct errors generated in the transmission line, which result in improving the quality of the transmission line.

Claims

1. A data error correction system comprising:

   a buffer for receiving data which are encoded by a block encoder and a convolutional encoder;

   a Viterbi decoder for decoding a block of the data designated from data output from said buffer in accordance with the Viterbi algorithm;

   a block decoder, which starts decoding when it receives data corresponding to a block code length from said Viterbi decoder, for executing the error correction when possible and outputting the result to a block decoder; and

   a control circuit for controlling execution of re-decoding by said Viterbi decoder so as to execute decoding by said block decoder for data corresponding to the block code length whose have yet to be corrected, based on a error detection signal output by said block decoder, when the error correction has not been possible.

2. A data error correction system according to claim 1, wherein the data error correction system allows repeated executions of decoding by the Viterbi decoder and the block decoder by said error detection circuit until the error correction is enabled, when the second error detection has not been possible.

3. A data error correction system according to claim 1, wherein the data input into said buffer is bit data expressed by soft decision representation.

4. A data error correction system according to claim 1, wherein said Viterbi decoder comprises:

a branch-metric generator for obtaining a probability of the case in which each transmittable symbol has been transmitted, when the data for respective symbols output from said buffer are received;

a path-metric register which stores the cumulative metrics of the survival path;

an addition comparison selection circuit for outputting a path-metric value at the n state and selection information at the n state selected by executing comparison, addition, and selection of outputs of said path-metric register and said branch-metric register at every symbol time along the trellis diagram;

a maximum likelihood path state number order detector for obtaining a state number which has the maximum path-metric value among path-metric values at the n state output from said addition comparison selection circuit;

a path memory for storing at every symbol time the selection information at the n state output from said addition comparison selection circuit;

a trace back circuit for outputting a decoded data with (u+k) bits from the last bit arrived when tracing back to the past from the state number output of the the maximum likelihood state number order detector at every (u+k) time, when the encoded data are divided at each k bits and u bits of redundancy bit are added; and

a decoding control circuit for allowing execution of re-decoding when receiving a control signal from said control circuit.

(54) Data error correction system

(57) A data error correction system is provided which is capable of executing repeated error correction processing, and which improves the quality of communication lines by allowing repeated corrections of errors generated in the transmission line.

The data error correction system comprises a Viterbi decoder 13 for decoding a designated encoded data from a buffer 12 and a block decoder for executing decoding of the data corresponding to a length of a block code after being decoded from the Viterbi decoder 13, when error correction is possible. When error correction is not possible, the data error correction system controls execution of re-decoding by the Viterbi decoder for executing error correction of the data corresponding to a length of a block code whose correction has not been possible yet at this stage.
